

What is Cirrhosis?

Written by: Alan Franciscus, Editor-in-Chief

Forward

The term cirrhosis is derived from the Greek term scirrhus and is used to describe the orange or tawny surface of the liver. Chronic hepatitis C infection can lead to liver damage through the development of fibrosis (scarring) tissue in the liver. After years or decades of infection liver fibrosis can become so extensive that the architecture of the liver is altered as a result of excessive scarring, development of small nodules, and changes in liver tissue. This is called cirrhosis. As cirrhosis further develops, scar tissue replaces healthy liver cells and the ability of the liver to perform its many functions is impaired. Of note, the damage to the liver is not only caused by the hepatitis C virus – the damage is also caused by the immune system attacking and destroying the liver cells where the hepatitis C virus has taken up residence. It is important to remember that the majority of people with hepatitis C do not develop cirrhosis. Hepatitis C is a slowly progressive disease and only about 10-25% of people with chronic hepatitis C develop cirrhosis, but this process usually takes many years or decades. However, we can not predict who will and who will not develop cirrhosis so it is important that people are monitored on a regular basis by their medical providers.

Chronic liver disease and cirrhosis is the 12th leading cause of death in the United States. The number of annual deaths attributed to HCV and cirrhosis is approximately 19,000. Hepatitis C is the most common cause of cirrhosis in the United States, followed by alcoholic liver disease. Other causes include non-alcoholic fatty liver disease (NAFLD), genetic disorders, hepatitis B, hepatitis D, drugs and toxins and other diseases or conditions not listed above. NAFLD is expected to be the leading cause of cirrhosis in the coming decades.

HCV Genotype

In general people with HCV genotype 3 have a faster disease progression to cirrhosis and liver cancer than HCV genotype 1. HCV genotype 2 has a lower risk of disease progression than HCV genotype 1.

What is Cirrhosis? —CONTINUED FROM PAGE 1

Cirrhosis is divided into two categories — compensated and decompensated.

Compensated Cirrhosis

Compensated cirrhosis means that the liver is heavily scarred but can still perform many important bodily functions. Many people with compensated cirrhosis experience few or no symptoms and can live for many years without serious complications. But it is important to remember that HCV disease progression is not linear; that is, the process speeds up so it is critical for people to take the necessary steps to make sure that they are receiving the appropriate medical care, which may include HCV therapy to help slow down or stop the disease progression process.

Decompensated Cirrhosis

Decompensated cirrhosis means that the liver is extensively scarred and unable to function properly. People with decompensated cirrhosis eventually develop many symptoms and complications that can be life threatening.

Symptoms and Complications of Decompensated Cirrhosis

Patients with decompensated cirrhosis develop a variety of symptoms such as fatigue, exhaustion, loss of appetite, nausea, jaundice, weight loss, stomach pain, impotence, bruising and bleeding, and other potentially life threatening symptoms.

Many complications can develop because the liver is unable to perform many of its important functions. Complications of cirrhosis can include:

- A combination of factors such as portal hypertension, low albumin levels and kidney dysfunction produce an accumulation of fluid in the body. Ascites is the accumulation of fluid in the abdominal cavity. Edema is the accumulation of fluid in the extremities, especially the feet and legs.
- Bleeding problems (coagulopathy) develop as

the liver is unable to produce clotting factors. In addition platelet (for blood clotting) count drops because of an enlarged spleen.

- As liver disease progresses there is bone mass and density loss.
- The spleen stores red and white blood cells and platelets. An enlarged spleen develops due to blood being forced into it when portal hypertension develops. An enlarged spleen loses its ability to store red and white blood cells, and platelets.
- Hardening of the liver due to dying liver cells can be felt on examination.
- A damaged liver is unable to regulate the production and breakdown of some female and male hormones. In women this can cause menstrual irregularities, and in men, gynecomastia (breast enlargement).
- Impaired mental status is due to many factors. Toxic substances such as ammonia that are usually filtered by the liver reach the brain. Symptoms of encephalopathy include personality changes, changes in sleep patterns, violent behavior, sluggish movements, drowsiness, confusion, stupor, and coma.
- Itching (pruritus) can develop that can be debilitating. The cause of pruritus is believed to be caused by impairment or failure of bile flow complicated by jaundice.
- Kidney function deteriorates in someone with decompensated cirrhosis, contributing to fluid retention (ascites, edema) and various kidney disorders.
- People with hepatitis C who develop cirrhosis are at risk for liver cancer.
- Muscle wasting can result from the inability of the liver to metabolize proteins, which can make a person with cirrhosis more prone to bone fractures.
- Scar tissue in the liver restricts the flow of blood and leads to portal hypertension resulting in complications such as ascites, spontaneous bacterial peritonitis, varices and other potentially life-threatening complications.

—CONTINUED

What is Cirrhosis? —CONTINUED FROM PAGE 2

- Spontaneous Bacterial Peritonitis is a condition caused when the body’s natural bacteria enters the ascites fluid causing severe infection.
- The veins in the stomach, esophagus and rectum become so stretched and dilated (due to portal hypertension) that a condition called varices develops which can lead to internal bleeding.

When the liver completely breaks down and it is unable to perform its job, it is called end-stage liver disease. The goal at this stage is to try to manage complications due to a deteriorating liver.

Treatment

Now, people are being treated at all stages of cirrhosis. Treatment with direct-acting antiviral (DAAs) medications is highly effective in people with cirrhosis. Successful treatment greatly reduces the risk of disease progression but it does not eliminate it. There is a chance that people will continue to develop more disease progression including liver cancer. This was the case with interferon-based therapies and it is the case with the current DAA-based therapy. For this reason people with severe fibrosis or cirrhosis prior to treatment with HCV medications should be evaluated by a liver specialist on a regular basis after being cured. There are monitoring guidelines available at the end of this fact sheet. It is also important to talk with your medical provider and share these guidelines with them before and after therapy.
